Paper type: Primary Research Article

Abstract

1 The relationship between population structure and demographic history is critical to
2 understanding microevolution and for predicting the resilience of species to
3 environmental change. Using mitochondrial DNA from extant colonies and radiocarbon-
4 dated subfossils, we present the first microevolutionary analysis of emperor penguins
5 (*Aptenodytes forsteri*) and show their population trends throughout the last glacial
6 maximum (LGM, 19.5 – 16 kya) and during the subsequent period of warming and sea
7 ice retreat. We found evidence for three mitochondrial clades within emperor penguins,
8 suggesting that they were isolated within three glacial refugia during the LGM. One of
9 these clades has remained largely isolated within the Ross Sea, while the two other clades
10 have intermixed around the coast of Antarctica from Adélie Land to the Weddell Sea. The
11 differentiation of the Ross Sea population has been preserved despite rapid population
12 growth and opportunities for migration. Low effective population sizes during the LGM,
13 followed by a rapid expansion around the beginning of the Holocene, suggest that an
14 optimum set of sea ice conditions exist for emperor penguins, corresponding to available
15 foraging area.

1 **Introduction**

2 Genetic data both from modern and subfossil samples, palaeo-ecological niche modeling,
3 and fossil evidence have become vital tools for reconstructing demographic histories (e.g.
4 woolly mammoths (*Mammuthus primigenius*) (Nogués-Bravo *et al.*, 2008) and lions
5 (*Panthera leo*) (Barnett *et al.*, 2014)). Indeed such studies have shown that species'
6 patterns of genetic diversity and distribution have varied dramatically under different
7 climatic regimes (Carstens & Richards, 2007). Climatic shifts have been one of the major
8 drivers of species' range shifts, fluctuations in abundance, species extinctions and also in
9 the formation of genetically distinct populations (Hewitt, 1996). As climate change and
10 habitat degradation potentially take us into the 6th mass extinction (Barnosky *et al.*, 2011),
11 it is critical that we understand how species have coped with change in the past to be able
12 to assess their likely responses and resilience to future climate change (Hoelzel, 2010).

13 Emperor penguins (*Aptenodytes forsteri*) are an iconic Antarctic species whose
14 population genetic structure has not been studied to date. We know little about dispersal
15 among colonies or how historical climate change may have affected their range and
16 abundance. Thus, we have limited capacity to predict how these birds may fare in the
17 future. Projections for continent-wide declines of emperor penguins have been made
18 based on the demographic responses of the Pointe Géologie colony to changes in sea ice
19 conditions (Barbraud & Weimerskirch 2001, Jenouvrier *et al.*, 2009, Ainley *et al.*, 2010,
20 Jenouvrier *et al.*, 2012, Jenouvrier *et al.*, 2014). However, decadal monitoring data is only
21 available for this single site out of 46 known emperor penguin colonies; as such, the
22 climate change responses of emperor penguins across their entire distribution and over
23 millennial timescales are currently unknown (Ainley *et al.*, 2010).

1 Emperor penguins are highly reliant on sea ice throughout most of their breeding cycle,
2 and mating and incubation takes place on land-fast sea ice in most of the known colonies
3 (Fretwell *et al.*, 2012, Fretwell *et al.*, 2014). During the breeding season, emperor
4 penguins feed on prey that is also sea ice dependent (Gales *et al.*, 1990). Significant areas
5 of open water exist year-round within the Antarctic sea ice zone in the form of leads and
6 polynyas (Zwally *et al.*, 1985 and references therein). These areas are often important in
7 providing emperor penguins access to their underwater foraging habitat when the fast ice
8 extends far from their colonies (Dewasmes *et al.*, 1980). Polynya formation is driven by
9 either upwelling of Circumpolar Deep Water or by the outflow of katabatic winds that
10 push sea ice away from the coastline (Martin, 2001). Polynyas are associated with
11 enhanced primary production, as the reduction in sea ice volume facilitates an earlier
12 spring melting of sea ice and a coincident earlier start in photosynthetic primary
13 productivity (Martin, 2001). Some polynyas are permanent features of the sea ice zone and
14 create areas of hyperproductivity, such as the Ross Sea polynya (Smith & Gordon, 1997),
15 whilst most are smaller and ephemeral features depending on wind stresses and currents.

16 Changes in the extent and duration of sea ice around Antarctica show highly regionalized
17 trends with some areas increasing or remaining stable while others are decreasing
18 (Vaughan *et al.*, 2013, Zwally *et al.*, 2002); this has an effect on the population dynamics
19 of emperor penguins as both positive and negative sea ice anomalies can result in
20 negative population growth rates at the local scale (Massom *et al.*, 2009, Ainley *et al.*,
21 2010, Barbraud *et al.*, 2011, Jenouvrier *et al.*, 2014). Despite uncertainties over the rate
22 and extent of ice loss that will occur around Antarctica, all climate models project a
23 reduction in the extent and duration of Antarctic sea ice by the end of the century (Collins
24 *et al.*, 2013). As sea ice declines we might expect emperor penguins to be disadvantaged
25 by a lack of breeding habitat (Jenouvrier *et al.*, 2014), unless they have the capacity to

1 alter their preferred choice of breeding site or their range by colonising new areas. Recent
2 studies have shown more plasticity than expected in the locations of breeding colonies;
3 satellite imagery suggests that colonies where the fast ice is inadequate at the onset of the
4 breeding season relocated or partially relocated onto ice shelves or ice-bergs (Fretwell *et*
5 *al.*, 2014, LaRue *et al.*, 2014). However, as sea ice declines, emperor penguins may also
6 have to contend with altered prey availability and face new threats from predators as
7 changing conditions differentially affect species at other trophic levels (Trathan *et al.*,
8 2011).

9 During the last glacial maximum (LGM, 19.5 – 16 kya), the winter sea ice extent was
10 approximately double the present day values, and seasonal variation in sea ice extent is
11 thought to have been greater (Gersonde *et al.*, 2005). It is unclear how this would have
12 affected emperor penguins. Thatje and colleagues (2008) suggested that they may have
13 migrated with the sea ice to lower latitudes, staying within energetic migration thresholds
14 of the ice edge, and could have maintained breeding populations around Antarctica by
15 foraging in the marginal ice zone at the sea ice edge. Alternatively, they could have
16 remained associated with polynyas. Sediment cores suggest the existence of LGM
17 polynyas in several locations, including the north-western Ross Sea, the south-eastern
18 Weddell Sea off Dronning Maud Land, and the north-western Weddell Sea (Mackensen
19 *et al.*, 1994, Brambati *et al.*, 2002, Thatje *et al.*, 2008, Smith *et al.*, 2010). In either case,
20 reductions in overall primary productivity within what is today's seasonal sea ice zone
21 (Domack *et al.*, 1998, Kohfeld *et al.*, 2005) would likely have been detrimental to
22 emperor penguin populations (Ainley *et al.*, 2010).

23 Little is known about the level of natal philopatry or migration among emperor penguin
24 colonies. Understanding philopatry is particularly important in light of population models
25 that suggest that emperor penguins may be declining as a result of local climatic shifts

(Jenouvrier *et al.*, 2009, Jenouvrier *et al.*, 2014). High emigration rates are conceivable amongst emperor penguin colonies; satellite tracking has shown that they travel thousands of kilometres on their juvenile journeys, often passing other colonies (e.g. Kooyman *et al.*, 1996, Thiebot *et al.*, 2013, Wienecke *et al.*, 2010). Generally, philopatry is high amongst penguins (Dehnhard *et al.*, 2014, Saraux *et al.*, 2011), but population structure is absent in many species (e.g. Chinstrap penguins (*Pygoscelis antarctica*) (Clucas *et al.*, 2014)) as even low levels of migration can be sufficient to homogenize populations (Hartl & Clark, 1997).

We analyzed the population structure among eight extant emperor penguin colonies (Figure 1) using mitochondrial DNA sequences, and inferred population trajectories during and since the LGM using a combination of ancient and modern DNA sequences in a Bayesian coalescent framework (Drummond *et al.*, 2005). This method reconstructs past changes in abundance by estimating the genealogy from sequence data, and co-estimating the effective population size at different points in time, where the effective population size is the number of individuals that contribute offspring to the descendant generation (Pybus *et al.*, 2000). We aimed to: 1) investigate how emperor penguin populations were affected by sea ice conditions during and following the LGM; and 2) to test the hypothesis that emperor penguins comprise one panmictic population as a result of the high dispersal of individuals after fledging, and the lack of obvious ecological barriers to dispersal around the Antarctic coastline.

Materials and methods

Sample collection

Skin tissue of dead emperor penguins was collected from Halley Bay (see Figure 1 for all sample locations) in November 2012 and transported frozen to the UK, where it was transferred to 90% ethanol and stored at -20°C. Blood samples were collected from Gould Bay in December 2013 and transported to the UK at ambient temperature in RNA later (Life Technologies), and then stored at -20°C. Shed feathers were collected from the Ross Sea between 2010 and 2012, and were transported and stored at -20°C. Shed feathers were collected at least 10 meters apart to minimize sampling the same bird. Pectoral muscle biopsies were collected from dead chicks at Fold Island in September 2010, from Pointe Géologie in December 2010 and from Amanda Bay in December 2012 and 2013. Biopsies were immediately placed in 90% ethanol and stored at -20°C. Whole dead chicks were collected from Auster in September and October in 1993 and 1994 and transported and stored at -20°C. Bones from the subfossil remains of three penguins were collected at Club Lake in January 2013 and stored at -80°C. Club Lake is an ice-free area in the Vestfold Hills which is currently unoccupied by penguins. The nearest extant colony is Amanda Bay, 95 km away.

Where blood samples were taken, one handler seized the upper body with both hands and restrained the flippers, with the bird's head placed under the arm of the handler to prevent biting and minimize stress (Le Maho *et al.*, 1992). The second handler took blood from the brachial vein using a 25G needle and 1 mL syringe. Total restraint time was generally two to three, but occasionally four, minutes. The bird was then released at the edge of the colony. Sampling was conducted under permits from the UK Foreign and Commonwealth Office, the US National Science Foundation and the Australian Antarctic Division. Each of these permits was issued following independent ethical review of the sampling. All

sampling was carried out in accordance with UK Home Office guidelines and also received ethical approval from the University of Oxford, British Antarctic Survey and Australian Antarctic Division. The radiocarbon ages, expressed here as years BP (i.e. before 1950), of the Club Lake remains were determined using accelerated mass spectrometry by GNS Science Rafter Radiocarbon National Isotope Centre, New Zealand. The apparent ages were corrected for the marine-carbon reservoir effect (Gordon & Harkness, 1992) using the calibration program Calib7.0 (ST UI & Reimer, 1993).

DNA extraction, amplification and sequencing

Genomic DNA (gDNA) was extracted from modern samples with the QIAGEN DNeasy Blood and Tissue Kit. The manufacturer's protocols for blood and tissue samples were followed with the following modifications to the digestion step: for blood samples 30 µL of proteinase-K was used and the digestion time was 3 h; for tissue samples 40 µL proteinase-K and an additional 10 µL 1 M dithiothreitol (skin samples only) was used with an incubation time of 32 h. All samples were treated with either 1 µL RNase A (QIAGEN) or 1 µL Riboshredder (Epicentre) according to the manufacturers' instructions. DNA was eluted in 100 µL of elution buffer following an incubation of 5 – 20 min. For subfossil samples ~50 mg of bone was decalcified in 0.5 M EDTA/0.001% Triton X100 at 56°C for 48 h and then extracted using a standard phenol chloroform protocol with ethanol precipitation and a final elution volume of 30 µL. The subfossil samples were extracted in a physically isolated laboratory which had not been used previously for avian samples to minimise the risk of contamination. The mitochondrial hypervariable region (HVR) and cytochrome B (CytB) were sequenced in all modern and ancient DNA samples. HVR is a rapidly evolving region of the mitochondrial genome, and so is suitable for investigations of recent demographic history, whilst CytB is a conserved gene and can hence give information about longer-term demographic history (Baker &

Marshall, 1997). HVR was amplified in all modern samples using primers F-0225 and R-INR (all primer sequences can be found in Supplementary Table 1). The reaction mix consisted of 7.5 μ L of PCR Master Mix (QIAGEN), 0.2 μ M of each primer, and 5 -10 ng gDNA, made up to 15 μ L with ddH₂O. Thermocycling conditions were: 94°C for 3 min; 35 cycles of 94°C for 30 s, 59.5°C for 45 s, 72°C for 1 min; followed by an extension period of 72°C for 10 min. Occasionally, double bands were apparent when the PCR product was visualized by electrophoresis. For these individuals, the shorter 755 bp band was extracted from the gel and purified using QIAGEN or Promega gel extraction kits following the manufacturer's instructions. For Fold Island, Amanda Bay, Auster and Pointe Géologie colonies, CytB was amplified using primers B1 (Baker *et al.*, 2006, Kocher *et al.*, 1989) and B6 (Baker *et al.*, 2006) with a reaction mix consisting of 7.5 μ L of GoTaq Green Master Mix (Promega), 0.2 μ M of each primer, and 5-10 ng gDNA, made up to 15 μ L with ddH₂O. Thermocycling conditions were: 95°C for 1 min; 35 cycles of 95°C for 20 s, 52°C for 40 s, 72°C for 50 s; then 72°C for 5 min. For the Cape Washington, Cape Crozier, Gould Bay and Halley Bay samples, primers CytB-F1 and CytB-R1 were used with a reaction mix consisting of 7.5 μ L of PCR Master Mix (QIAGEN), 0.2 μ M of each primer, and 5 -10 ng gDNA, made up to 15 μ L with ddH₂O. Thermocycling conditions were: 94°C for 3 mins; 35 cycles of 94°C for 45 s, 60°C for 45 s, 72°C for 1 min; then 72°C for 10 min. For the subfossil samples we designed novel, species-specific primers (Supplementary Table 1) to amplify short (<150bp) overlapping fragments in order to improve the success rate of amplification from degraded DNA. The reaction mix consisted of 7.5 μ L of AmpliTaq Gold 360 Master Mix (Life Technologies), 0.2 μ M of each primer, and 25-50 ng gDNA, made up to 15 μ L with ddH₂O. Thermocycling conditions were: 95°C for 10 min; 42 cycles of 95°C for 20 s, T_m (primer) for 20 s, 72°C for 20 s; 72°C for 5 min. PCR products for Fold Island, Amanda Bay,

1 Auster, Pointe Géologie and the subfossil samples were bi-directionally sequenced by the
2 Australian Genome Research Facility (AGRF) via the Sanger sequencing method using
3 the PCR primer pairs. PCR products for Gould Bay, Halley Bay, Cape Washington and
4 Cape Crozier were sequenced using the Sanger method by Macrogen Europe. The reverse
5 primer for the HVR and the forward primer for CytB were used to sequence each product
6 twice, as these were found to work best in the sequencing reaction. Geneious v5.5.9 was
7 used for alignment. A high number of heteroplasmic sites were found in the HVR and
8 these were re-scored manually according to IUPAC ambiguity codes. No heteroplasmic
9 sites were recorded in the CytB sequences.

10 ***Data analysis – summary statistics and population structure***

11 Arlequin v3.5 (Excoffier & Lischer, 2010) was used to calculate summary statistics for
12 HVR, CytB, and concatenated HVR and CytB. jModeltest (Posada & Buckley, 2004)
13 was used to estimate the best substitution model for each dataset, and then the following
14 corrections for calculating genetic distances were implemented in Arlequin: HVR -
15 Tamura correction with a gamma distribution for rate heterogeneity with $\alpha = 0.016$; CytB
16 – Tamura correction; concatenated – Tamura correction with a gamma distribution for
17 rate heterogeneity with $\alpha = 0.109$ (Tamura, 1992). Arlequin was also used to calculate
18 pairwise genetic distances (θ_{ST}) between colonies and perform analyses of molecular
19 variation (AMOVA) on the concatenated sequences with the Tamura & Nei correction.
20 Network v4.612 (Fluxus Technology Ltd.) was used to draw haplotype networks.

21 ***Data analysis - demographic histories***

22 Bayesian phylogenetic analyses and demographic reconstructions were performed using
23 BEAST v1.8 (Drummond *et al.*, 2012). The dataset was partitioned into HVR and CytB,
24 with a nucleotide substitution model of HKY (Hasegawa *et al.*, 1985) with four gamma
25 categories for HVR and TN93 (Tamura & Nei, 1993) for CytB, with ambiguous states

permitted. We used the coalescent Extended Bayesian Skyline Plot tree prior (Heled & Drummond, 2008) with a strict molecular clock. For molecular clock calibration, the HVR substitution rate prior was specified as a normal distribution around a mean value of 0.55 substitutions/site/Myr (SD = 0.15), to reflect the substitution rate of the HVR in Adélie penguins (*Pygoscelis adeliae*) (Millar *et al.*, 2008). In the absence of a published substitution rate for CytB in penguins we used a uniform prior of 5×10^{-4} to 5×10^{-1} substitutions/site/Myr with a starting value of 2×10^{-2} (Weir & Schluter, 2008). The corrected radiocarbon ages of the Club Lake samples were input as tip dates, for additional calibration of the molecular clock. Based on these initial priors, substitution rates for our dataset were estimated during the analysis. The posterior distributions of substitution rates, phylogenetic trees and effective population size through time were generated using the Markov chain Monte Carlo (MCMC) sampling procedure, implemented in BEAST, which was run for 120 million generations with samples drawn every 6000 steps and the first 10% discarded as burn-in. Tracer v.1.5 was used to check effective sample size (ESS) values to confirm convergence with all values >200. Three independent BEAST analyses were performed to ensure reproducibility of the posterior distribution. The population size parameter of the demographic model ($N_e * \tau$) was converted to N_{ef} by dividing the parameter by 14 years, which is the estimated generation length of emperor penguins (Forcada & Trathan, 2009, Jenouvrier *et al.*, 2005). Phylogenetic trees were visualised using FigTree v1.4.

Results

Present day population structure

We sequenced 226 individuals from eight colonies (Figure 1) plus three subfossil birds whose ages ranged from 643 – 881 years BP (after correction for marine reservoir effect).

We sequenced 629 bp of the mitochondrial hypervariable region (HVR) and 867 bp of cytochrome *b* (CytB) from each individual (GenBank accession numbers KP644787 - KP645015 and KP640645 - KP640873, respectively). Genetic diversity was extremely high for the HVR, with 220 haplotypes recorded out of the 229 individuals sequenced; the mean number of pairwise differences between haplotypes was 20.62 ± 9.14 (Table 1).

Genetic diversity was much lower for CytB, with just 59 unique haplotypes recorded.

Our results show a high level of gene flow among all the EAWS colonies (East Antarctica including Adélie Land, and the Weddell Sea) and between the two Ross Sea colonies (Table 2), but little exchange between the EAWS and Ross Sea colonies (pairwise θ_{ST} values range from 0.213 to 0.617, Table 2). When colonies are grouped into two populations (Ross Sea and EAWS), a high proportion (17.7%) of the genetic variation is explained by the difference between the groups, and there is strong and significant genetic differentiation between them (AMOVA, $F_{ST} = 0.196$, $p < 0.001$). This pattern is also evident from haplotype networks (Supplementary Figures 1 & 2), which show that Ross Sea individuals tend to be closely related, whilst sequences from EAWS colonies tend to cluster independently from the Ross Sea haplotypes. However, some Ross Sea sequences are found across the network, and vice versa. This could indicate low-level gene flow between the Ross Sea and EAWS.

Population history with respect to climate change

There is evidence of past population expansion in emperor penguins across Antarctica as indicated by our Extended Bayesian Skyline Plots (EBSPs) (Figure 2). An almost nine-fold increase in abundance of the EAWS population commenced approximately 12 kya. The Ross Sea population expanded three-fold from approximately 9.5 kya. Superimposing expansion signals over the estimated temperature derived from ice cores (Figure 2c), it is clear that population expansion followed the end of the LGM. Tajima's D and Fu's F_S statistics provide further support for an expansion of both populations (Table 1).

Our phylogenetic analyses indicate three highly supported clades (Figure 3), which diverged during the Late Pleistocene (97 kya, 95% HPD: 50–154 kya). One of these clades is comprised predominantly of Ross Sea penguins, whereas the other two are dominated by EAWS individuals.

Discussion

This first analysis of emperor penguin population structure shows colonies within the Ross Sea are genetically distinct from other Antarctic colonies, whereas those from the rest of the continent and spanning up to 8000 km of coastline are panmictic (Table 2).

The admixture of the EAWS emperor penguins supports our hypothesis of limited population structure and indicates a very large dispersal range for the species. Given our genetic evidence of extensive mixing across Antarctica, the unique structure in the Ross Sea emperor penguins is surprising, and interestingly the same pattern was reported for the sympatric Adélie penguin (Ritchie *et al.*, 2004), providing further evidence that the Ross Sea has a unique evolutionary history.

The existence of distinct penguin populations in the Ross Sea is puzzling. There are neither geographic nor oceanographic barriers isolating the Ross Sea from the rest of Antarctica. Furthermore, the relative distance between the Ross Sea and other colonies does not adequately explain its isolation as, for example, the Pointe Géologie colony is approximately 5600 km closer to the Ross Sea colonies than to those in the Weddell Sea (Figure 1). Emperor penguins are known for their extraordinary migrations; satellite tracking showed that juveniles can travel >7000 km in eight months (Thiebot *et al.*, 2013). These observations support our genetic results for the EAWS region and indicate juvenile emperor penguins could comfortably traverse the 1800 km between Pointe Géologie and the Ross Sea colonies. There are also no clear habitat, environmental or foraging differences between the Ross Sea colonies and those located elsewhere (Budd, 1961, Smith *et al.*, 2012), except that Ross Sea colonies are located closer to the ice edge, and are therefore potentially more resilient to increases in sea ice. We suggest that the divergence of emperor penguins into two populations is historical in origin.

1 There are three ancestral lineages within modern emperor penguins, providing evidence
2 that populations were isolated in the past (Figure 3) and diverged through
3 microevolutionary processes, such as selection or genetic drift, which occur more rapidly
4 in small, isolated populations (Hewitt, 2000). One of these lineages is mostly limited to
5 the Ross Sea, indicating that the isolation of this region has persisted through time.
6 Indeed, emperor penguins occupying the Ross Sea may have become so differentiated
7 that interbreeding with the EAWS penguins occurs at very low rates, perhaps because of
8 genetic, behavioural (Templeton, 1981) or cultural incompatibilities, such as the timing of
9 breeding or the development of regional dialects (de Dinechin *et al.*, 2012, Jouventin &
10 Aubin, 2002, MacDougall-Shackleton & MacDougall-Shackleton, 2001).

11 Emperor penguins use complex display calls to recognise their mates and offspring
12 (Robisson *et al.*, 1993). Vocalisation is known to be an important part of the courtship
13 process for most penguins (Richdale, 1944, Waas *et al.*, 2000). Interestingly, royal
14 penguins (*Eudyptes schlegeli*) respond more strongly to calls from their own colony
15 members than to calls originating from different colonies, suggesting differences in
16 dialect (Waas *et al.*, 2000). Differences in vocalisations have also been found among
17 gentoo penguin (*Pygoscelis papua*) populations (de Dinechin *et al.*, 2012). If dialects
18 become too different, then courtship may be inhibited, thereby limiting interbreeding.
19 This has been observed in passerine birds, in which genetically distinct groups have
20 unique mating songs (MacDougall-Shackleton & MacDougall-Shackleton, 2001).
21 Emperor penguin vocalisation patterns have only been recorded at Pointe Géologie
22 (Robisson *et al.*, 1993), but our hypothesis could be explored in the future by comparing
23 vocalisations of emperor penguins from the Ross Sea with those of other colonies.

24 Although the isolation and differentiation of the Ross Sea emperor penguins has persisted,
25 the other two historical lineages show no geographic bias and have now hybridized to

1 form one EAWS population. Incomplete mixing of ancestral lineages is typical of species
2 that have survived the Pleistocene ice-ages in multiple refugia (Hewitt, 1996). Our EBSPs
3 indicate that both the EAWS and Ross Sea populations had reduced effective population
4 sizes during the LGM (Figure 2). Thus, contrary to a hypothesis that emperor penguins
5 would benefit from glaciation as a result of reduced competition with other predators
6 (Thatje *et al.*, 2008), it seems that they, like other Antarctic and sub-Antarctic penguin
7 species (Clucas *et al.*, 2014, Ritchie *et al.*, 2004, Trucchi *et al.*, 2014), were adversely
8 affected by the LGM.

9 We propose that both the reduced abundance and divergence into three lineages were
10 linked to breeding and foraging habitat availability. Today emperor penguins have a
11 circumpolar distribution with suitable habitat spanning the entire continent (Fretwell &
12 Trathan, 2009). However, Antarctica during the LGM looked very different than the
13 continent we know today (Figure 4). Most of the continental shelf was covered by ice as a
14 result of both the extension of ice-sheets and thick, perennial sea ice, which reduced
15 productivity south of the modern-day Polar Front drastically (Anderson *et al.*, 2002,
16 Anderson *et al.*, 2009, Domack *et al.*, 1998, Gersonde *et al.*, 2005, Kohfeld *et al.*, 2005,
17 Samuel Jaccard pers. comm.). We suggest that the increased sea ice extent would have
18 severely restricted the foraging habitat available for emperor penguins and, coupled with
19 lower primary production, could have resulted in a scarcity of prey resources.

20 Additionally, air temperatures were approximately 13°C colder than the present day
21 (Jouzel *et al.*, 2007), which may have been near the penguins' lower limit of temperature
22 tolerance (Le Maho *et al.*, 1978), potentially impacting both breeding success and adult
23 survival.

24 The extent and duration of sea ice are important factors in the breeding success of
25 emperor penguins (Massom *et al.*, 2009). Emperor penguins require stable fast ice to

1 breed, but they have to traverse the sea ice to establish colonies in autumn and to forage
2 in winter and spring. The distances between the colonies and potential foraging areas can
3 influence breeding success where the fast ice extent is variable (Massom *et al.*, 2009), but
4 not in locations where the extent is relatively stable (Robertson *et al.*, 2013). We therefore
5 expect that if the winter sea ice extent was substantially greater in the LGM, or if the
6 timing of sea ice retreat was altered, that this would have made some of the extant colony
7 locations energetically untenable during the LGM.

8 During the LGM, the summer sea ice extent was similar to what we observe today,
9 whereas the winter extent was roughly doubled (Gersonde *et al.*, 2005). Colonies may
10 have been located close to the continent so that the ice remained stable throughout the
11 breeding season, but this would have required adults to walk immense distances to reach
12 foraging areas during winter and spring while provisioning the chick. In that case, the
13 chicks would receive fewer meals and be less likely to survive. The present distribution of
14 colonies close to land (Fretwell & Trathan, 2009) suggests that fast ice proximate to land
15 provides a more stable platform than near the fast ice edge. Also, stable ice close to the
16 coast occurs in predictable locations that might be important for colony establishment and
17 cohesion. Colonies further away from the coast may therefore be difficult to maintain.
18 Our discovery of three distinct lineages provides evidence against a straightforward,
19 latitudinal range shift in line with the sea ice edge, and suggests that emperor penguins
20 may have survived the LGM in three suitably situated, geographically isolated refugia.

21 Emperor penguin refugia during the LGM may have been linked to the presence of
22 polynyas. Several extant emperor penguin colonies are located near polynyas, which may
23 be utilised for foraging during the winter (Croxall *et al.*, 2002). Polynyas acted as “hot
24 spots” of primary productivity during the LGM, supporting marine life and flying
25 seabirds (Thatje *et al.*, 2008). Sediment cores in the north-western Ross Sea indicate open

1 water polynya conditions throughout the LGM (Brambati *et al.*, 2002, Thatje *et al.*, 2008)
2 and this polynya could have sustained a refuge population until the Ross Sea began to
3 clear of ice (Figure 4). By 9.6 kya most of the northern Ross Sea was open water (Licht &
4 Andrews, 2002). The retreating sea ice and increased upwelling during deglaciation
5 increased productivity in the Ross Sea (Anderson *et al.*, 2009) and likely increased the
6 foraging habitat and prey availability to emperor penguins, therefore we hypothesise that
7 these factors drove the three-fold expansion of emperor penguins in this region around
8 this time (Figure 2). The LGM polynya may have also supported Adélie penguins,
9 accounting for the existence of a distinct Ross Sea clade as previously observed for this
10 species (Ritchie *et al.*, 2004).

11 Another polynya was located in the south-eastern Weddell Sea off Dronning Maud Land
12 (DML) (Mackensen *et al.*, 1994, Thatje *et al.*, 2008) (Figure 4). Colonies of snow petrels
13 (*Pagrodroma nivea*) were present in DML throughout the LGM, associated with this
14 polynya (Wand & Hermichen, 2005), and it may have also provided a refuge for emperor
15 penguins. There is evidence from sediment cores for a third LGM polynya, located in the
16 north-western Weddell Sea (Smith *et al.*, 2010) (Figure 4); this would be consistent with
17 our third emperor penguin refuge, given that the refuge is likely to be more proximate to
18 DML than the Ross Sea, since the two refugial lineages hybridized post-glacially while
19 the Ross Sea lineage remained distinct.

20 We propose that two refuge populations that were isolated in the Weddell Sea expanded
21 their range into Prydz Bay and Adélie Land and merged during the retreat of the East
22 Antarctic ice sheet 14 – 7 kya (Mackintosh *et al.*, 2011). At this time, the onset of more
23 favourable environmental conditions could have resulted in the dramatic, nine-fold
24 increase in abundance shown here (Figure 2). A seasonal sea ice cycle was established in
25 Prydz Bay approximately 10.4 kya (Barbara *et al.*, 2010), opening up foraging habitat and

1 coinciding with high levels of primary productivity (e.g. (Anderson *et al.*, 2009, Sedwick
2 *et al.*, 2001). In Adélie Land, primary productivity and the duration of the ice-free season
3 increased from 9 kya (Denis *et al.*, 2009a, Denis *et al.*, 2009b). This new habitat could
4 have facilitated the range expansion of the EAWS lineages.

5 It should be noted that the timing of the abundance increase of emperor penguins does not
6 coincide exactly with the end of the LGM (Figure 2). We hypothesise that it is not the
7 temperature change itself, but rather the subsequent change in sea ice conditions and
8 primary productivity that are most likely to affect emperor penguins. Indeed, it has been
9 proposed that there is an optimal level of sea ice at the large temporal / spatial scale for
10 emperor penguins, which roughly corresponds to current conditions (Ainley *et al.*, 2010).
11 Therefore, the greater sea ice extent of the LGM was most likely sub-optimal for emperor
12 penguin populations. The end of the LGM is measured when temperatures began to
13 increase (19 – 16 kya). However deglaciation, during which ice-sheets and sea ice
14 retreated and primary productivity increased, occurred slowly over an extended time
15 period (*ca.* 17 – 11 kya) (Anderson *et al.*, 2009). These events occurred later in the Ross
16 Sea than in East Antarctica, and our results support the hypothesis that ice-sheet and sea
17 ice retreat and increasing primary productivity were the main factors controlling emperor
18 penguin abundance, as the Ross Sea emperor penguin population expanded later than the
19 EAWS population (Figure 2). Furthermore, emperor penguins produce only one chick per
20 year and take approximately five years to reach sexual maturity (Jenouvrier *et al.*, 2005),
21 so any abundance increase would be initially slow.

22 Our hypothesis of three refugial populations of emperor penguins during the LGM could
23 be tested using a higher density of genetic markers. This would allow for the investigation
24 of clinal variation in genetic diversity arising from founder effects as new areas were
25 colonized following the expansion from refugia after the LGM (Hewitt, 1996). It should

1 be noted that our present study is based on mitochondrial DNA and therefore represents
2 dispersal patterns of females only, but nonetheless supports a plausible explanation for
3 past and present microevolutionary processes in emperor penguins. The next step should
4 be to verify these findings using nuclear markers to account for male-mediated gene flow.

5 In this continent-wide study of microevolution in an Antarctic penguin we suggest that
6 past climatic changes have greatly impacted emperor penguin populations. As conditions
7 became more favourable after the LGM, their global population expanded and the
8 populations from the Weddell Sea and East Antarctic intermixed to form one large,
9 panmictic population. Interestingly, the isolation of the Ross Sea emperor penguins has
10 persisted until today. The reasons for this isolation remain unknown, but we suggest that
11 separate management plans are required for the Ross Sea and EAWS populations. By
12 conserving the full spectrum of genetic variation and, in particular, all phylogeographic
13 lineages, the evolutionary potential of the species can be maximised (D'Amen *et al.*,
14 2013).

15 Our study suggests that emperor penguins have shown important historic responses to
16 past climate shifts and their population increase post-LGM was remarkable. However, the
17 projected rate of temperature increase over the next century is an order of magnitude
18 greater than that following the LGM (Collins *et al.*, 2013, Masson-Delmotte *et al.*, 2013,
19 Shakun *et al.*, 2012). At present, emperor penguins become heat stressed around 0°C, so
20 may exist near the upper limits of their physiological tolerance (Wienecke, pers obs).

21 Whether the resilience demonstrated in the past of this highly cold-adapted species will
22 enable it to adapt to projected climate change remains to be seen, as rising temperatures
23 will alter its breeding grounds and foraging space more rapidly than in the past.

Acknowledgements

We gratefully acknowledge the assistance of Dick Filby, Antarctic Network International for collecting samples from Gould Bay and Hannah Macleod for assistance in the field, Françoise Amélineau for samples from Pointe Géologie, James Bumac for sample collection at Fold Island, British Antarctic Survey staff at Halley Bay, Roger Kirkwood for sample collection at Auster, and Paul Ponganis and the NSF for facilitating feather collection in the Ross Sea (NSF 09-44220). We thank John van den Hoff for his insights regarding Antarctic refugia, Gareth Dyke for commenting on earlier drafts of the manuscript and Samuel Jaccard for advice regarding LGM primary productivity estimates. We are also grateful to Simon Foote for providing key infrastructure and to Patrick Lelliott for his assistance in the laboratory. This project was funded by Australian Antarctic Science Project 4184 (KM, BW, JY), ANZ Trustees Holsworth Wildlife Research Endowment (JY), NERC and Penguin Lifelines (GVC), British Antarctic Survey Ecosystems Programme (PNT) and the Darwin Initiative (TH).

Figure Legends

Figure 1: Sample locations of emperor penguin colonies. The number of sequences obtained from each location is shown in brackets. Red points indicate the origin of modern samples, the blue point indicates the origin of the subfossil samples.

Figure 2: Extended Bayesian skyline plots showing the change in effective female population size (N_{ef}). Solid lines show the median estimate; dotted lines show the 95% highest posterior density interval. a) EAWS colonies; b) Ross Sea colonies; c) the Antarctic temperature anomaly (the difference from the average of the last 1000 years) as estimated from the EPICA Dome C ice core (Jouzel *et al.*, 2007), with the ice core location indicated in red.

Figure 3: Phylogenetic relationships among individuals. Magenta - EAWS individuals; green - Ross Sea individuals; blue – subfossil individuals. The posterior probabilities are shown for the major, strongly supported clades.

Figure 4. Schematic of contemporary population structure and reconstruction of historical conditions. Sampled colonies are indicated by dots, as in Figure 1. The magenta and green shading indicates population structure as estimated from this study. Lines represent the sea ice edge, as in Gersonde *et al.*, 2005. M-SSI = modern summer sea ice edge; LGM-SSI = LGM summer sea ice edge; M-WSI = modern winter sea ice edge; LGM-WSI = LGM winter sea ice edge, ? = insufficient data to reconstruct the sea ice edge. Penguins represent hypothesised locations of polynya refugia. Emperor penguin picture: © Samuel Blanc / www.sblanc.com.
